(Rceived 21 December 2017; published 4 May 2018)

We present the first experimental confirmation of the quantum-mechanical prediction of stronger-than-binary correlations. These are correlations that cannot be explained under the assumption that the occurrence of a particular outcome of an $n \geq 3$-outcome measurement is due to a two-step process in which, in the first step, some classical mechanism precludes $n-2$ of the outcomes and, in the second step, a binary measurement generates the outcome. Our experiment uses pairs of photonic qutrits distributed between two laboratories, where randomly chosen three-outcome measurements are performed. We report a violation by 9.3 standard deviations of the optimal inequality for nonsignaling binary correlations.

DOI: 10.1103/PhysRevLett.120.180402

Introduction.—Quantum mechanics is so successful that it is difficult to imagine how to go beyond the present theory without contradicting existing experiments. However, going beyond our present understanding of quantum mechanics can enable us to solve long-standing problems like the formulation of quantum gravity. Some of the most puzzling questions in quantum theory are connected to the measurement process [1]. To go beyond our present understanding of measurements, we use recent axiomatizations of quantum theory [2–6] that identify quantum theory as a special case within the general probabilistic theories. We identify an axiom related to the structure of measurements that can be modified in a way not contradicting existing experimental evidence, but making different predictions.

In quantum theory, two-outcome measurements are described by pairs of operators, $(E, \mathbb{1} - E)$. A quantum measurement is feasible whenever both operators are positive semidefinite. Conversely, in any general probabilistic theory, if $(E_1, E_2, \ldots, E_n)$ represents a feasible $n$-outcome measurement, then any postprocessing to a two-outcome measurement $(E_1', E_2')$ is also a feasible measurement. However, according to quantum theory, $(E_1, E_2, \ldots, E_n)$ is already a feasible $n$-outcome measurement whenever all postprocessings to a two-outcome measurement $(E', \mathbb{1} - E')$ are feasible. This suggests a natural alternative, namely, that feasible $n$-outcome measurements are only those that can be implemented by selecting from two-outcome measurements. Such measurements are hence binary [7] and can be implemented as a two-step process in which, in the first step, some classical mechanism excludes all but two of the outcomes and, in a second step, the final output is produced by a genuine two-outcome measurement. The concept is illustrated in Fig. 1.

Correlations between the outcomes of measurements performed by two parties, called Alice and Bob, are described by joint probabilities $P(a, b|x, y)$, where $x$ and $y$ are Alice’s and Bob’s measurement settings, respectively, and $a$ and $b$ are Alice’s and Bob’s measurement outcomes, respectively. “Binary nonsignaling correlations” are those which are both nonsignaling, i.e., $\sum_b P(a, b|x, y) \equiv P_A(a|x)$ and $\sum_a P(a, b|x, y) \equiv P_B(b|y)$, and have only two nontrivial outcomes, i.e., $P_A(a|x) = 0$ except for two outcomes $a$ and $P_B(b|y) = 0$ except for two outcomes $b$, and the convex hull thereof [7]. Such correlations also include cases that are forbidden in quantum theory as, for example, Popescu-Rohrlich boxes [8] maximally violating the Clauser-Horne-Shimony-Holt inequality [9]. Interestingly, according to quantum theory, there exist stronger-than-binary nonsignaling correlations [7]. A major problem, however, has been to identify how they can be actually observed.

The experiment presented here aims at the maximum violation predicted by quantum theory of the optimal and unique inequality [10] satisfied by binary nonsignaling correlations. The experiment is a bipartite Bell-type experiment in which Alice randomly chooses between two different measurements, $x = 0, 1$, each of them with three possible outcomes, $a = 0, 1, 2$, and Bob randomly chooses between two different measurements, $y = 0, 1$, each of
and the outcomes $a = 2$ and $b = 2$ do not occur explicitly (see below). In contrast, according to quantum theory, the maximal value for $I_a$ is

$$I_a = 2(2/3)^{3/2} \approx 1.089.$$  

This maximum quantum value can be achieved by preparing two qutrits in a particular state and making some particular three-outcome local measurements (see below).

In the experiment, we have obtained

$$I_a = 1.066 \pm 0.007,$$

which implies a violation of the inequality in Eq. (1) with a statistical significance corresponding to 9.4 standard deviations. A further analysis of the data (see below) shows that residual systematic errors do not explain this violation.

Consequently, general probabilistic theories in which $n$-outcome measurements are only binary are falsified by showing that there are correlations that are not binary nonsignaling. This also shows that, in nature, there are genuinely ternary measurements, thus demonstrating that the measurement process in quantum theory cannot be explained as a two-step process as in Fig. 1(a). In fact, the result of the experiment demonstrates that none of the four measurements (Alice’s or Bob’s) can be binary.

**Bound on binary nonsignaling correlations.**—The bound $I_a \leq 1$ in Eq. (1) has been proved in Ref. [10] by computer-based methods. Here we prove explicitly that the bound $I_a \leq 1$ in Eq. (1) is valid for binary nonsignaling correlations. We proceed by defining the auxiliary quantities

$$X_A = \sum_{a,b,x,y:a\neq b} (-1)^{a+x+y}P(a,b|x,y)$$  

(5a) and

$$X_B = \sum_{a,b,x,y:b\neq a} (-1)^{b+x+y}P(a,b|x,y).$$  

(5b)

These clearly obey $X_A = 0$ and $X_B = 0$ for all nonsignaling correlations. We then have the inequality

$$3I_a - X_A - X_B \leq \sum_{a,b,x,y} P(a,b|x,y) \equiv 4,$$

(6)

which holds because the left-hand side of Eq. (6) has only coefficients ±1. Consequently, $I_a \leq \frac{1}{3}$ holds for all nonsignaling correlations.

For the bound on binary nonsignaling correlations, it is enough to consider the extremal correlations. By definition, for those there exist certain indices $a_x \in \{0,1,2\}$ for $x = 0, 1$ and $b_y \in \{0,1,2\}$ for $y = 0, 1$ such that $P(a,b|x,y) = 0$ holds whenever $a = a_x$ or $b = b_y$. The reminder of the entries are then extremal two-outcome correlations and hence are either deterministic, $P(a,b|x,y) \in \{0,1\}$, or they form a Popescu-Rohrlich box [8], implying $P(a,b|x,y) \in \{0,\frac{1}{2}\}$. As a consequence, the bound on $I_a$ must be a multiple of $\frac{1}{3}$ and must not exceed $\frac{1}{3}$. This proves $I_a \leq 1$ for binary nonsignaling correlations. This bound is also tight, as can be seen by considering the outcome assignment $a = x$ and $b = 2y$.

**Experimental test.**—Our experimental setup is described in Fig. 2 and further develops techniques from Refs. [11–13] optimized for testing the prediction in Eq. (3). The source generates the two-photon state

$$|\psi\rangle = (\sqrt{2}|H_aH_a\rangle + |V_aV_a\rangle - |H_bH_b\rangle)/(2),$$

(7)

where $H_a$ ($V_a$) denotes horizontal (vertical) polarization in the upper path and $H_b$ denotes horizontal polarization in the lower path. Consequently, $|H_a\rangle$, $|V_a\rangle$, and $|H_b\rangle$ define a qutrit for Alice and for Bob. The visibility of the entangled state is $0.98 \pm 0.01$. Each photon of the pair is distributed to a different laboratory and measured there locally.
In each laboratory, the settings 0 and 1 are chosen randomly by means of a random number generator. The measurement outcomes for setting 0 are projectors onto the one-dimensional spaces spanned by

$$|\eta_{00}\rangle = (2|H_u\rangle - (1 + \sqrt{3})|V_u\rangle - (1 - \sqrt{3})|H_l\rangle)/\sqrt{12},$$

$$|\eta_{10}\rangle = (2|H_u\rangle - (1 - \sqrt{3})|V_u\rangle - (1 + \sqrt{3})|H_l\rangle)/\sqrt{12},$$

$$|\eta_{20}\rangle = (|H_u\rangle + |V_u\rangle + |H_l\rangle)/\sqrt{3},$$

where the projector onto $|\eta_{k0}\rangle$ corresponds to outcome $k$. Similarly, for setting 1,

$$|\eta_{01}\rangle = (2|H_u\rangle + (1 + \sqrt{3})|V_u\rangle + (1 - \sqrt{3})|H_l\rangle)/\sqrt{12},$$

$$|\eta_{11}\rangle = (2|H_u\rangle + (1 - \sqrt{3})|V_u\rangle + (1 + \sqrt{3})|H_l\rangle)/\sqrt{12},$$

$$|\eta_{21}\rangle = (|H_u\rangle - |V_u\rangle - |H_l\rangle)/\sqrt{3},$$

These settings together with the state $|\psi\rangle$ yield the maximal quantum value of $I_q$; see Eq. (3). In our setup, the detectors D1–D3 correspond to outcomes 0–2 for Alice and the detectors D4–D6 correspond to outcomes 0–2 for Bob. The measurements are complete with respect to the qutrit space spanned by $|H_u\rangle$, $|V_u\rangle$, and $|H_l\rangle$, while any component of the incoming photon that is outside of the qutrit space remains undetected. In addition, the imperfect efficiency of the detectors, together with the coincidence logic, yield an overall detection efficiency of 0.087 ± 0.001. We account for both effects by implementing the fair sampling assumption, that the coincidences recorded are a representative subsample of what would have been recorded, if all photons were detected.

Data are collected in 4500 runs, with a collection time of 0.5 s for each run. Within each run, the measurement settings of Alice and Bob remain fixed. In total, 75,544 coincidences have been recorded.

Evaluation of the data.—The 4500 runs with random measurement settings for Alice and Bob, combine to 1060 complete data sets with all four combinations of settings and an average of 67.1 coincidences and for each complete set. We evaluate three conditions on the data: (i) normalization, i.e., whether \( \sum_{a,b} N_r(a, b|x, y) \) is independent of \( x \) and \( y \); (ii) nonsignaling, i.e., whether \( \sum_{a,b} N_r(a, b|x, y) \) is independent of \( x \) and \( \sum_{a,b} N_r(a, b) \) is independent of \( y \); and (iii) binary correlations, tested by means of the inequality

\[
\sum_{k,x,y=0,1} (-1)^{k+x+y} N_r(k, k|x, y) - \frac{1}{4} \sum_{a,b,x,y} N_r(a, b|x, y) \leq 0.
\]

(10)

Hereby \( N_r(a, b|x, y) \) denotes the number of coincidences for each of the complete data sets \( r = 1, \ldots, 1060 \) when the outcome of Alice (Bob) is \( a \) (\( b \)) and the setting is \( x \) (\( y \)). We compute the mean \( m \) and the variance \( v \) over the 1060 runs for each condition, so that \( t = m \sqrt{1060/v} \) is distributed according to the Student-\( t \) distribution with \( g = 1059 \) degrees of freedom. In this regime, after rescaling by \( \sqrt{(g-2)/g} \), the Student-\( t \) distribution is very close to a normal distribution. We therefore obtain the \( p \)-value of the joint conditions (i) or (ii) using the \( \chi^2 \) distribution, where there are three independent conditions in (i) and 11 independent conditions in (ii). The obtained values are given in Table II as “Full data set.”

The full data set shows a violation of the inequality in Eq. (10) with a significance corresponding to 9.4 standard deviations. However, also the nonsignaling conditions (ii) are violated by 3.6 standard deviations. The origin of this apparent signaling is the unavoidable fluctuations in the pumping laser. This leads to statistically significant (apparent) signaling since the statistical error is smaller than the error due to the imperfections. A maximum-likelihood fit imposing the nonsignaling constraints increases the value of \( I_a \), so that we conclude that the significance of the violation of \( I_a \) is nonetheless genuine. To further support this assertion, we reduce the set of samples so that the statistical error is again dominant and consider a reduced data set with only one-fifth of the complete data sets; see Table II, “Reduced data set.” There, although the shot noise is increased by a factor of \( \sqrt{5} \approx 2.2 \), a violation of the inequality in Eq. (10) by 4.6 standard deviations remains, while the violation of the nonsignaling conditions becomes negligible.

Finally, we compute the empirical frequencies

\[
P_r(a, b|x, y) = \frac{N_r(a, b|x, y)}{\sum_{a',b'} N_r(a', b'|x, y)}
\]

(11)

for each \( r \). This allows us to compute for each repetition the value of \( I_a \). In Eq. (4) and Table II, we report the resulting mean value and standard error.

Conclusion.—We have presented an experimental violation with pairs of entangled qudits of the optimal inequality for nonsignaling binary correlations. Our result (i) provides compelling evidence against two-step explanations of the measurement process, (ii) falsifies nonsignaling binary theories as possible descriptions of nature, apart from the detection and locality loopholes, and (iii) shows, apart from these loopholes, that in nature there exist stronger-than-binary nonsignaling correlations, i.e., correlations that, in particular, cannot be reproduced using Popescu–Rohrlich boxes. The experiment also illustrates how the maturity and refinement achieved by the experimental techniques developed for quantum communication and quantum information processing can be used to test
subtle predictions of quantum theory and obtain detailed insights about how nature works.

Data repository.—The complete data set is publicly available by following the link in Ref. [14]. We encourage readers who want to expand our work with further data analysis to do so.
